METHOD AND APPARATUS FOR RESURFACING BRAKE ROTORS

CROSS-REFERENCE TO RELATED APPLICATIONS

This application is related to, and claims priority from, U.S. Provisional Patent Application Ser. No. 60/489,639 filed on Jul. 24, 2003, and herein incorporated by reference.

STATEMENT REGARDING FEDERALLY SPONSORED RESEARCH

Not Applicable.

BACKGROUND OF THE INVENTION

The present invention relates to automotive vehicle brake lathes configured for resurfacing brake rotor components, and in particular, to an improved on-car brake lathe apparatus and a method for compensating for runout between an on-car brake lathe and a vehicle wheel hub to which the on-car brake lathe is secured for a brake rotor resurfacing operation.

One of the main components of a wheel braking system employing rotor brakes are the brake rotors, which provide a solid rotating surface against which the stationary brake friction pads are clamped or compressed to generate a frictional force, slowing the rotational movement of the brake rotors and the associated vehicle wheels. The brake rotors are subjected to repeated and substantial frictional forces by the brake friction pads, and over time, become worn. Uneven application of braking force, debris, or uneven frictional surfaces on the brake friction pads can result in the formation of grooves, channels, or scratches in the surfaces of the brake rotors. Repeated heating and cooling of the brake rotor resulting in extreme temperature variations can additionally result in the lateral warping of the brake rotor.

A worn or warped brake rotor may be resurfaced by cutting or grinding to provide a uniform smooth brake friction pad contact surface if sufficient brake rotor material remains to provide an adequate braking surface without compromising the structural integrity of the vehicle braking system. However, once a brake rotor has been worn below a minimum safety thickness, it is unable to safely dissipate the heat generated by a brake application, and must be replaced.

To provide for a uniform surface, any abnormalities in the brake rotor, such as a lateral warping must be detected and removed during the resurfacing procedures. An additional source of lateral warping defects in a brake rotor or brake rotor is often over tightened attachment bolts or an uneven mounting surface onto which the brake rotor is secured in the vehicle wheel assembly. If the brake rotor is removed from the vehicle wheel assembly for a resurfacing operation on a fixed “bench” brake lathe any abnormalities or defects resulting from the mounting of the brake rotor to the vehicle wheel assembly may not be accurately identified or corrected during the resurfacing procedure. Accordingly, a variety of brake resurfacing machines or brake lathes have been developed to resurface brake rotors while they remain mounted to the vehicle wheel assembly.

Brake resurfacing machines or brake lathes configured to resurface brake rotors mounted to a vehicle wheel assembly are commonly referred to as on-car brake lathes. Examples of an on-car brake lathe include the OCL-360 and OCL-400 brake lathes sold by Hunter Engineering Co. of Bridgeton, Mo. By eliminating the need to remove the brake rotor from the vehicle wheel assembly, the overall efficiency of the resurfacing procedure is improved, and the chances for operator induced error are reduced. However, the resurfacing of brake rotors which remain mounted to the vehicle wheel assembly requires that the on-car brake lathe and the vehicle wheel assembly, including the brake rotor, be aligned along a common axis, typically, the rotational axis of the vehicle wheel assembly hub onto which the on-car brake lathe is secured.

Often, the hub surface to which the vehicle wheel assembly mounts is not aligned within a required tolerance to the axis of rotation for the axle upon which the vehicle wheel assembly is secured. This deviation between the hub surface and the axis of rotation for the wheel assembly is referred to as lateral runout, and must be compensated for either manually or automatically before beginning the resurfacing procedures with the on-car brake lathe.

Manual runout compensation procedures are tedious and complex. First, an operator secures the output spindle of the on-car brake lathe to the vehicle wheel hub using a suitable adapter. Next, a motor in the on-car brake lathe is activated to rotate the output spindle, the adapter, and brake rotor. Any runout present in the system is directly measured by one or more measurement devices, which provide the operator with a suitable visual indication representative of the actual runout experienced by the on-car brake lathe as the adapter is rotated through one or more complete rotations. Using the visual indication, the operator manually adjusts one or more mechanical adjustment elements, such as screws or dials, altering the rotational axis of the on-car brake lathe output spindle to reduce the observed runout to within an acceptable tolerance for performing the resurfacing of the brake rotor.

To reduce the observed runout to within the desired tolerances using the manual runout compensation procedure usually requires several iterations when carried out by a skilled operator. The extra time spent by an operator to setup the on-car brake lathe and perform the manual runout compensation can substantially increase the time required to completely resurface brake rotors, resulting in a corresponding increase in cost and lost productivity.

Accordingly, a number of on-car brake lathe devices have been configured with active automatic runout compensation mechanisms which do not require significant operator input. Such active automatic runout compensation mechanisms are shown in European Patent Application No. 1 017 343 A1 to Costanzo & Meccanica Carole S.p.A., based on Italian Patent No. 0248591 Y1, and in U.S. Pat. No. 6,101,911 to Newell et al. The automatic runout compensation mechanism shown in the ‘911 Newell et al. patent includes at least one adjustment rotor interposed between a pair of adapters and which is concentric about an axial drive shaft. The on-car brake lathe motor and cutting elements are secured to one adapter, and the entire mechanism secured to the vehicle wheel hub via the second adapter. The adjustment rotor includes a slanted surface in engagement with either a second adjustment rotor having an opposing slanted surface or one of the adapters. An adjustment mechanism is utilized to alter the rotational orientation of the adjustment rotor about the axis of the axial drive shaft.

As the components of the ‘911 Newell et al. automatic runout compensation mechanism are rotated about the axis at a fixed speed of 120 RPM, runout is detected by an accelerometer. A processor receives an output signal from the accelerometer and provides corresponding control signals to an adjustment mechanism. Alteration of the rotation position of the adjustment rotor about the axis of the axial drive shaft as the components are rotated at the relatively high fixed rotational speed of 120 RPM compensates for the detected runout by attempting to alter the angle at which the two slanted
surfaces are engaged, and correspondingly the angle between the first and second adapters. Due to significant high speed vibrations and the interaction of the various rotating components, such as bearings, gears, and shaft, errors are induced in the automatic runout compensation sensor signals. Thus, automatic runout compensation typically requires several complete rotations of the various components about the axis before the adjustment rotor rotational position is sufficiently altered to compensate for any detected runout.

The automated adjustment mechanism of the '911 Newell et al. patent associated with the use of the one or more slant rotors is a costly and complex mechanical arrangement. The mechanism requires an initial phasing or alignment of the adjustment rotors, followed by a lengthy trial-and-error adjustment process to compensate for any detected runout.

Accordingly, there is a need for an on-car brake lathe having improved precision runout compensation mechanisms, which are not subjected to rotational movement noise and vibrations during runout measurements, and which can quickly and accurately compensate for detected runout, but which do not require complex and costly components.

With conventional on-car brake lathes, it is necessary to invert the orientation of the lathe when switching between sides of a vehicle. Inverting the lathe inverts the operator control panel, and can render the operation of the controls difficult, particularly as the number of controls or displays increased. Accordingly, there is a further need for an on-car brake lathe having a control panel which is adjustable so as to be presentable to an operator at a selected orientation, independent of the orientation of the on-car brake lathe.

Traditionally, on-car and bench brake lathes utilize motors or drive systems configured for operation at a fixed spindle RPM and feed rate. During rotor cutting or resurfacing, a resonance or vibration, commonly referred to as "chatter", can develop between the rotor cutting tools and the rotor surface, resulting at best in an uneven resurfacing of the brake rotor, or at worst, in severe damage to the rotor surface or rotor cutting tools themselves. Accordingly, the fixed spindle RPM and feed rates in traditional on-car and bench brake lathes are selected to be below the rates at which the resonance or vibration is likely to occur. Alternatively, such as shown in U.S. Pat. No. 6,591,729 B1 to Greenwald et al., vibration damping or attenuating components such as pads or elastomeric bands are brought into contact with the brake rotor during resurfacing to control or reduce undesired "chatter" resonance or vibrations.

Since it is known that "chatter" vibrations or resonances are a function of the spindle RPM, feed rates, and depth of the resurfacing cut, it would be advantageous to provide on-car and bench brake lathes with a reliable system to detect the presence of "chatter" vibrations or resonance during the cutting of the rotor, and to configure the brake lathes with one or more automatic adjustments to reduce or eliminate the vibrations before it affects the quality of the surface finish on the rotor. Since the rates at which the resonance or vibration are likely to occur vary for brake rotors of different sizes, thicknesses, and materials, it would be advantageous to provide an on-car brake lathe which is capable of varying the spindle RPM during the resurfacing of a brake rotor and, optionally, the linear feed rate of the cutting implements, up to a maximum rate at which a desired brake rotor resurfacing quality can be achieved, thereby reducing operator time required to resurface a brake rotor.

It is desirable to provide an adjustable brake resurfacing system with sensor signals that function when the cut is completed and automatically stop the operation of the brake lathe, thereby reducing the time required for the operator to prepare the brake lathe to cut the next rotor.

Some vehicles are equipped with locking differentials in the vehicle drive train that engage when a difference in wheel rotational speed from one side of the vehicle to the other reaches approximately 100 RPM. When the locking mechanism engages, as may occur during rotation of a brake rotor by an on-car brake lathe, the resulting change in rotational resistance can violently rotate the entire on-car brake lathe body. It is desirable to provide an on-car brake lathe with safety features configured to automatically stop the lathe rotation if a sudden resistance is encountered in the cut.

With a variety of information related to vehicle specifications, including brake rotor thicknesses and dimensions, it would be advantageous to provide a brake lathe system with a communication interface by which the lathe can acquire at least vehicle specifications from a data network or other automotive service device. It is also desired that this communication system would be able to send data to a remote printer or console.

U.S. Pat. No. 6,363,821 B1 to Greenwald et al. discloses a vehicle brake lathe incorporating cutting tip contact sensors to provide signals to a controlling microprocessor to facilitate automated movement of the cutting tips relative to a brake rotor surface, as well as a determination of a depth of cut. However, the '821 Greenwald et al. patent does not appear to provide the brake lathe operator with a simple and efficient indication of contact between each individual cutting tip and the brake rotor surface. Accordingly, there is a need to provide improved feedback from an operating brake lathe to an operator, permitting proper adjustments of the cutting tips for depth of cut and runout measurement during rotor resurfacing, and ensuring proper engagement between a visually occluded cutting tip and a brake rotor surface without requiring an operator to move to within close proximity of rotating components during an adjustment or resurfacing procedure.

In addition to identifying contact between the cutting tips and a brake rotor surface, it is useful to provide a displayed measure of a depth of cut provided by the cutting tips. U.S. Pat. No. 6,363,821 B1 to Greenwald et al. provides a displayed depth of cut utilizing a displacement gauge positioned relative to each tool holder on a brake lathe. The displacement gauge in the '821 Greenwald, et al. patent directly measures the spatial separation or displacement between the two tool holders. To obtain a depth of cut measurement, an initial separation distance between the cutting bits is compared with a subsequent separation distance after a depth of cut adjustment has been made to a cutting bit. The calculated change in separation distance corresponds to the change in depth of cut of the cutting bit from the initial position plus the depth of cut for the opposite cutting bit (which is zero if it has not yet been adjusted). Hence, the position of both tool holders must be monitored to provide a depth of cut measurement for a single tool holder. Accordingly, it would be advantageous to provide a simplified depth-of-cut measurement system for a single tool holder on a brake lathe which does not require information related to the position of a second tool holder, or a measurement of displacement between a pair of tool holders, to provide a depth of cut measurement.

**BRIEF SUMMARY OF THE INVENTION**

Briefly stated, the present invention is an improved brake lathe system for the resurfacing of work pieces such as vehicle brake rotors. The improved brake lathe system is configured with a variable speed variable speed spindle motor...
and controller for regulating at least the work piece cutting rate and providing automatic shutdown of the brake lathe system when predetermined conditions are met, such as completion of a brake rotor resurfacing cut or detection of an abnormal operating condition.

In an alternate embodiment, a brake lathe of the present invention incorporates a variable speed spindle motor as a drive motor. Sensors incorporated into the brake lathe are configured to detect vibrations generated by the cutting tips when in contact with the work piece or brake rotor surface, and provide a feedback signal which is utilized to control the variable speed spindle motor RPM and optionally, the linear feed rate of the cutting tips. Preferably, the variable speed spindle motor is operated to provide a maximum RPM and feed rate at which the cutting tip vibrations are maintained below a predetermined threshold. The sensor signal will fall to a minimum level when the cut has ended, signaling the motor controller to stop operations.

In an alternate embodiment of the present invention, an on-car brake lathe is provided with a precision runout compensation system. The precision runout compensation system electronically directs a variable speed spindle motor to rotate the wheel coupling components of the on-car brake lathe to, and stops at, at least three discrete positions about an axis of rotation to obtain runout measurements after the on-car brake lathe has been coupled to a brake rotor. A sinusoidal representation of the runout present between the on-car brake lathe drive axis and the brake rotor rotational axis is calculated, and the variable speed spindle motor is again activated to rotate to, and stop the wheel coupling components at an adjustment position at which a single operator adjustment to the wheel coupling components can compensate for the runout present between the brake rotor and the wheel coupling components of the on-car brake lathe.

In an alternate embodiment, a brake lathe of the present invention incorporates a cutting tip contact indicator to provide an operator with a visual or audible indication of contact between each cutting tip and surface of a workpiece or brake rotor. Each cutting tip is electrically coupled, through a power source, to an indicator circuit and to an electrical ground. Contact between a cutting tip and the workpiece or brake rotor provides a complete electrical circuit between the electrical ground and the power source, resulting in an electrical current flow through an associated indicator circuit. Preferably, the associated indicator circuit incorporates one or more LEDs, which are correspondingly illuminated to provide the operator with a visual confirmation of contact between the cutting tip and the workpiece or brake rotor surface.

In an alternate embodiment, an on-car brake lathe of the present invention incorporates a cutting tip contact indicator to provide an operator with a visual or audible indication of contact between each cutting tip and surface of a workpiece or brake rotor. Sensors incorporated into the on-car brake lathe are configured to detect vibrations generated by the cutting tip in contact with the workpiece or brake rotor surface, and provide feedback signals which are utilized correspondingly to illuminate one or more LEDs to provide the operator with a visual confirmation of contact between the cutting tip and the workpiece or brake rotor surface. Such an audible indication thereof is also provided.

In an alternate embodiment, an on-car brake lathe of the present invention provides the operator with a depth of cut display. The information shown on the depth of cut display is based on signals received from a rotary encoder operatively coupled to the end of a threaded shaft upon which the cutting blade tool holders are disposed.

In an alternate embodiment, an on-car brake lathe of the present invention provides the operator with a rotor runout display. The information shown on the rotor runout display is based on signals received from a rotary encoder operatively coupled to the end of a threaded shaft upon which the cutting blade tool holders are disposed.

In an alternate embodiment, a brake lathe of the present invention is configured with a processor and associated communications circuits for exchanging information with one or more automotive service devices, such as a vehicle wheel aligner, vehicle wheel balancer, or automotive shop management system. The brake lathe is preferably configured to receive brake rotor specifications, such as diameter and thickness, and may be configured to communicate brake rotor resurfacing results to a display on the lathe or a remotely disposed printer or console. The processor may be further configured to utilize the received brake rotor specifications to establish limits on the range of movement for the cutting blade tool holders, or to establish an initial cutting speed and/or feed rate for a variable speed variable speed spindle motor.

In an alternate embodiment, a brake lathe of the present invention is configured with a control panel which is adjusted about an axis of rotation, to an orientation selected by the operator for ideal use and viewing independent of an orientation of the lathe body.

The foregoing and other objects, features, and advantages of the invention as well as presently preferred embodiments thereof will become more apparent from the reading of the following description in connection with the accompanying drawings.

DESCRIPTION OF THE PREFERRED EMBODIMENT

The following detailed description illustrates the invention by way of example and not by way of limitation. The description clearly enables one skilled in the art to make and use the invention, describes several embodiments, adaptations, variations, alternatives, and uses of the invention, including what is presently believed to be the best mode of carrying out the invention.

Refering to FIGS. 1 and 2, an on-car brake lathe 10 of the present invention is shown mounted to a transport trolley 12 for positioning adjacent a vehicle to be worked on (not shown). The on-car brake lathe 10 includes a support structure 14, onto which is mounted a variable speed drive spindle motor 16, an adjustable cutting head 18, and an output spindle 20. The variable speed spindle motor 16 is coupled to the output spindle 20 through a conventional drive mechanism (not shown) contained within the support structure 14, to rotate the output spindle 20 about a drive axis DA, and to linearly feed the cutting head 18 through a predetermined cutting range CR. An aligning joint 22 is secured to the output spindle 20, concentric with the drive axis DA, and includes an adapter 23 adapted to couple the output spindle 20 to a vehicle wheel hub or brake assembly (not shown).

Additionally included on the support structure 14 is an operator console or electrical enclosure 24. An operator interface 26 is mounted to the electrical enclosure 24. The operator interface 26, shown in FIG. 3, preferably includes at least a bar graph LED display 28 and a numerical LED display 30, and may optionally include one or more additional visual display elements 32 configured to provide the operator with information associated with the operation of the on-car brake lathe 10. For example, multiple visual display elements 32 in the form of single LED lights may be disposed on the operator interface 26 to assist an operator in performing a runout compensation procedure when coupling the on-car brake lathe 10 with a vehicle brake assembly, or to indicate the presence of a chatter condition during a resurfacing procedure.

In order for the adjustable cutting head 18, consisting of a pair of cutting tool holders 19, to engage a vehicle brake assembly (not shown), it is necessary for the on-car brake lathe 10 to be positioned to avoid interference with the vehicle brake caliper, vehicle suspension components, and vehicle body surfaces adjacent the vehicle brake assembly. Accordingly, it is often necessary to utilize the on-car brake lathe 10 in an upright position when resurfacing brake rotors on one side of a vehicle, and to utilize the on-car brake lathe 10 in an inverted position when resurfacing brake rotors on the opposite side of the vehicle. To facilitate operator access to the operator interface 26, the electrical enclosure 24 is rotationally coupled to the on-car brake lathe 10 about a shaft 35, shown in FIG. 4, and is adjustable about a rotational axis EA of the shaft 35, parallel to the drive axis DA, so as to present the operator interface 26 at a selected orientation, independent of the orientation of the on-car brake lathe 10, such as shown in FIG. 5. This enables the on-car brake lathe 10 to be utilized in either an upright configuration, or in an inverted configuration, shown in phantom in FIG. 5, as is sometimes required to facilitate engagement of the adjustable cutting head 18 with a vehicle wheel brake rotors.

Returning to FIG. 3, operator input controls 34 are additionally included on the operator interface 26. The operator input controls 34 preferably include at least a start button 34A, a stop button 34B, a spindle speed control knob 34C, a compensation button 34D, and a runout test button 34E.

Included within the electrical enclosure 24, as shown in FIG. 4, is a processor board 36 and motor controller 38. The processor board 36 incorporates a microprocessor 40, which may be a micro-controller, digital signal processor, or other logic circuit having sufficient capacity to control the functions of the on-car brake lathe 10, and is configured to access and execute instruction sets stored in a suitable electronic memory 40A, such as a RAM, ROM, EPROM, or EEPROM.

As shown in FIG. 6, the microprocessor 40 is operatively coupled to the motor controller 38 and to an LED drive circuit 42 for controlling the operation of the LED bar graph display 28, LED numeric display 30, and any additional visual display elements 32. The microprocessor 40 is additionally operatively coupled to receive signals from the operator input controls 34. One or more data lines 44 operatively couple the microprocessor 40 to the motor controller 38. The data lines 44 may optionally include a digital to analog converter circuit 46, and/or an analog optical isolator circuit 48, depending upon the particular input requirements of the motor controller 38. The motor controller 38 is in turn, coupled to the variable speed spindle motor 16 to provide electrical power to the motor windings (not shown), thereby controlling the motor output.

As is further seen in FIG. 6, the microprocessor 40 may be operatively coupled to receive input from, or exchange data with, one or more additional components of the on-car brake lathe 10 during operation of the on-car brake lathe 10, as is described below. These components may include, but not limited to, a motor shaft rotational position encoder 50, a lathe tilt angle sensor 52, an vibration sensor or accelerometer 54, a communications circuit 56 such as an RS422 port, or other optional encoder circuits 58, or an inclinometer 62. A suitable power supply 60 for the microprocessor 40 and associated circuits, such as a transformer or AC/DC converter, is provided on the processor board 36.

Preferably the microprocessor 40 is configured to monitor the rotational speed of the variable speed spindle motor 16 using the motor shaft rotational position encoder 50, which is operatively coupled to the shaft of the motor engaged with the output spindle 20. A representation of the rotational speed of the motor 16 may be displayed to an operator by the microprocessor 40 using either the LED bar graph display 28 or the LED numeric display 30. The microprocessor 40 regulates the input signal representative of a desired rotational speed to the motor controller 38, and adjusts the input signal in order to reach or maintain a desired rotational speed or torque of the output spindle 20. The output signal of the motor shaft rotational position encoder 50 is further utilized by the microprocessor 40 to monitor and control the rotational position of the output spindle 20 about an arc of less than 360 degrees, such as for use during runout compensation procedures.

In addition to providing control signals to the motor controller 38 in response to signals from the motor shaft rotational position encoder 50, the microprocessor is preferably configured to provide motor speed controls signals in...
response to signals received from a potentiometer coupled to the spindle speed control knob, permitting an operator to manually indicate or select a desired rotational speed for the motor and/or output spindle. A representation of either the actual rotational speed of the motor or the desired rotational speed as indicated by an operator using the spindle speed control knob, may be displayed on either the LED bar graph display or the LED numeric display by the microprocessor.

The microprocessor monitors an output from the tilt angle sensor during the lathe runout compensation procedures and during normal operation of the on-car brake lathe. In the event the signals from the tilt angle sensor indicate that the on-car brake lathe inclination has tilted or rotated beyond a predetermined inclination limit, the microprocessor is preferably configured to signal the motor controller to promptly cease rotation of the variable speed spindle motor, preventing a potentially dangerous situation. For example, if a vehicle lacking differential engages during a brake rotor resurfacing procedure with the on-car brake lathe coupled to the vehicle wheel hub, the resulting change in rotating mass can cause the on-car brake lathe to rotate violently about the drive axis DA, potentially causing serious injury to an operator, damage to the vehicle, or damage to the on-car lathe.

In an alternate embodiment, the on-car brake lathe is provided with a simple tilt sensitive switch (not shown) which is responsive to the inclination of the on-car brake lathe structure to switch between an engaged and disengaged configuration. By disposing the tilt sensitive switch in the power line to the variable speed spindle motor, upon inclination of the on-car brake lathe structure beyond a predetermined inclination, the tilt sensitive switch stops a flow of electrical current to the motor as a safety measure.

During a workpiece or brake rotor resurfacing procedure, undesired “chatter” resonance or vibrations may occur which can result in poor quality resurfacing of the brake rotor surface by the cutting head, or damage to either the brake rotor or brake lathe components. The “chatter” resonance or vibrations are a function of the spindle RPM, the cutting head linear feed rate, and the depth of cut by the cutting tips. Preferably, a feedback signal representative of a level of “chatter” resonance or vibrations is provided to the microprocessor by one or more suitable sensors. These sensors may include a microphone, an accelerometer, a piezo-electric device, a biased coil, proximity sensor, or any other suitable sensor capable of detecting the “chatter” resonance or vibrations generated by the cutting tips when in contact with the workpiece or brake rotor surface.

The microprocessor is preferably configured to respond to signals indicating the “chatter” resonance or vibrations have exceeded a predetermined threshold by directing the motor controller to alter either the cutting speed and/or the linear feed rate of the cutting tips. As shown in FIG. 3, a “chatter” LED warning light is optionally controlled by the microprocessor to provide the operator with a suitable warning upon the detection of a chatter condition during a workpiece or rotor resurfacing procedure.

In one embodiment, an on-car brake lathe of the present invention configured with a variable speed spindle motor, is operated during a brake resurfacing procedure by the microprocessor, at a maximum spindle RPM and linear feed rate for the cutting tips at which the cutting tip vibrations are maintained below a predetermined threshold, i.e., below an acceptable “chatter” level. Those of ordinary skill in the art will recognize that the microprocessor may be configured to begin a brake resurfacing procedure at a maximum spindle RPM and/or linear feed rate, and reduce the rate until the cutting tip vibrations are maintained below a predetermined threshold, i.e., below an acceptable “chatter” level. Alternatively, the microprocessor may be configured to begin the brake resurfacing procedure at a low or minimum spindle RPM and/or linear feed rate, and increase the rate until the cutting tip vibrations exceed a predetermined threshold, i.e., an acceptable “chatter” level, at which point the microprocessor directs the motor controller to reduce the rate.

In an alternate embodiment, an on-car brake lathe of the present invention configured with a drive system or variable speed spindle motor, is operated during a brake resurfacing procedure by the microprocessor with a continuously varying spindle RPM. Since it is known that “chatter” is a resonance condition, varying the spindle RPM continuously during a rotor resurfacing procedure prevents the cutting tip vibrations from developing a “static” or standing-waveform conditions in which “chatter” or other resonance conditions can exceed a predetermined threshold. Preferably, the microprocessor is configured to control the drive system or variable speed motor to continuously vary the spindle RPM within a predetermined cutting speed window or range, for example, ±6 RPM from an established cutting speed of the spindle during a rotor resurfacing procedure.

For brake lathe systems with an automatic depth of cut control, the microprocessor may be configured to further respond to the detection of “chatter” resonance or vibrations exceeding a predetermined threshold by reducing the depth of cut of the cutting head.

In addition to regulating the rotational speed of the spindle through the motor control, the microprocessor may optionally be configured to regulate the linear feed rate of the cutting head. As shown in FIG. 7, linear movement of the cutting head may be controlled by the microprocessor in a stepwise fashion. After each complete rotation of the vehicle brake rotor 75 as driven by the output spindle 20 (not shown in FIG. 7), the linear position of the cutting head is adjusted, resulting in the cutting tips 19 removing surface material from both sides of the brake rotor 75 in concentric circles. Alternatively, shown in FIG. 8, the linear movement of the cutting head may be controlled by the microprocessor in a smooth continuous fashion. During each rotation of the vehicle brake rotor 75 as driven by the output spindle 20 (not shown in FIG. 8), the linear position of the cutting head is continuously advanced (or retracted), resulting in the cutting tips 19 removing surface material from both sides of the brake rotor 75 along a continuous spiral path.

During operation, the on-car brake lathe is detachably secured to a vehicle wheel brake rotor on a vehicle axle in a conventional manner as shown in FIG. 9. An adapter 77 is initially secured to the vehicle wheel brake rotor 75 using the vehicle wheel lug nuts or retaining bolts. Next, the on-car brake lathe 10 is moved into position such that the aligning joint 22 and drive axis DA are substantially co-linear with a central axis of the rotor-mounted adapter 77, substantially corresponding to a rotational axis of the vehicle wheel brake rotor 75. A threaded retaining shaft (not shown) is passed axially through the support structure and output spindle and engaged with an axial threaded receiving bore (not shown) in the rotor-mounted adapter. Tightening of the threaded retaining shaft secures the rotor-mounted adapter against the aligning joint 22, and secures the on-car brake lathe to the vehicle wheel brake rotor to be resurfaced, enabling the vehicle wheel brake rotor 75 to be rotated by the variable speed motor of the on-car brake lathe 10.

As shown in FIG. 10 through FIG. 12, the preferred aligning joint 22 of the present invention comprises a front flange...
11
100, configured to seat against the rotor-mounted adapter 77 and configured for attachment to the output spindle 20. The front flange 100 is operatively coupled to the rear annular member 102 with a non-rotating connection. The connection between the front flange 100 and the rear annular member 102 is configured to permit adjustment of the relative inclination between the front flange 100 and the rear annular member 102, using a single adjustment bolt 104.

An adjustment ring 106 is located in an annular recess defined by the front flange 100 and the rear annular member 102 when assembled together. Adjustment ring 106 is free to rotate with respect to the front flange 100 and the rear annular member 102. The adjustment ring 106 contains a pair of fixed wedges 108, a centering bearing 110, and an adjustment wedge 112. The fixed wedges 108 are secured in a permanent position on the adjustment ring 106 by screws 114. The adjustment wedge 112 is secured loosely to the adjustment ring 106 by the adjustment bolt 104.

The bearing 110 maintains the adjustment ring 106 centered in the annular recess so that the adjustment ring 106 is free to rotate. The bearing 110 is secured in the adjustment ring 106 by a spring 116 and a set screw 118.

During use the output spindle 20 is rotated automatically to an adjustment position by the variable speed spindle motor 16. The adjustment ring 106 is then rotated by the operator so that the adjustment wedge 112 is brought into an adjustment position. The adjustment bolt 104 is rotated to bring a tapered surface 120 of the adjustment wedge 112 into contact with the front flange 100 and rear annular member 102. The angle of the tapered surface 120 of the adjustment wedge 112 is greater than the angle of tapered surfaces 122 on each of the fixed wedges 108. This allows the fixed wedges 108 to make full contact with the front flange 100 and the rear annular member 102; the adjustment wedge 112 begins to change the angle of inclination between the front flange 100 and the rear annular member 102. This is necessary to provide stability to the adapter.

After the fixed wedges 108 seat against the front flange 100 and rear annular member 102, the adjustment wedge 112 is forced between the front flange 100 and the rear annular member 102 by the adjustment bolt 104. The action of the adjustment wedge 112 being forced between the front flange 100 and the rear annular member 102 results in a change in the angle of inclination.

In an alternative embodiment, the adjustment bolt 104 and adjustment wedge 112 of the aligning joint 22 are replaced with a threaded screw or similar mechanism oriented parallel to the drive axis DA. Movement of the threaded screw parallel to the drive axis DA directly alters the relative inclination between the front flange 100 and the rear flange 102, allowing for compensation for the differences between a wheel rotational axis and the drive axis DA of the on-car brake lathe 10, i.e., runout compensation.

A method of the present invention for compensating for the differences between a wheel rotational axis and the drive axis DA of the on-car brake lathe 10 involves initially coupling the on-car brake lathe 10 to the adapter 77 mounted to the wheel hub with the aligning joint 22 placed between the rotor adapter 77 and the output spindle 23 as described in above. The adjustment ring 104 is initially free to rotate about the drive axis DA relative to the front flange 100 and the rear flange 102, and the single adjustment bolt 106 loosened to permit retraction of the adjustment wedge 108 from contact with the front flange 100.

After the on-car brake lathe 10 is attached to the vehicle, the operator levels an inclinometer 62 within the electronic enclosure 24 using an adjustment knob 120 to ensure that it is within an operating range. This is done by adjusting the position of the inclinometer 62 until the microprocessor 40 illuminates a level indicator 341, shown in FIG. 3, or another suitable indicator is provided to the operator. Preferably, to begin the compensation procedure, the variable speed spindle motor 16 is actuated to rotate the output spindle 20 through several complete rotations to "seat" all of the components and to eliminate any binding or stress associated with the attachment of the on-car brake lathe 10 to the vehicle.

To initiate the compensation procedure, the operator actuates an appropriate control 34D, such as shown in FIG. 3. The microprocessor 40 directs the variable speed variable speed spindle motor 16 to operate at a slow speed to sequentially rotate the output spindle 20, and thereby the aligning joint 22 and the vehicle brake rotor 75, to three unique rotational positions about the drive axis DA, stopping at each position to permit a steady-state runout measurement to be acquired.

Preferably, each of the three unique rotational positions is separated by approximately 120 degrees of rotation, and to reach each unique rotational position, the output spindle 20 is rotated through at least one complete revolution about the drive axis DA. At each rotational position, the rotation is stopped, and a stationary or steady-state angular measurement representative of runout is obtained by the inclinometer 62. Those of ordinary skill in the art will recognize that any of a variety of measurements which are representative of runout may be obtained at each rotational position.

Each steady-state angular measurement is associated with an identified rotational position, as indicated by the motor shaft encoder 50 operatively coupled to the output spindle 20. From the three angular measurements and associated rotational positions, a sinusoidal representation of runout at any rotational position about the drive axis DA is calculated by the microprocessor 40, and a single adjustment rotational position for adapter 22 is identified.

Methods and procedures for calculating a sinusoidal representation of runout are set forth in U.S. Pat. No. 5,052,111 to Carter et al., U.S. Pat. No. 5,029,395 to Braun, U.S. Pat. No. 4,180,915 to Lill et al., and U.S. Pat. No. 4,138,825 to Pelta, each herein incorporated by reference. Those of ordinary skill in the art will recognize that a variety of methods for measurement of lateral runout, requiring a different number of angular, or distance, measurements at a variety of different rotational positions, may be employed with the on-car brake lathe 10 of the present invention to facilitate lateral runout compensation adjustment.

Once the sinusoidal representation of runout has been determined by the microprocessor 40, the variable speed spindle motor 16 is actuated at the direction of the microprocessor 40 to rotate the output spindle 20, and thereby the aligning joint 22 and the vehicle brake rotor 75, about the drive axis DA, until the identified single adjustment rotational position is aligned with a predetermined alignment position, preferably top dead center of the spindle rotation axis DA.

With the adjustment ring 104 rotated to the predetermined alignment position, preferably a top-dead-center position, the adjustment bolt 106 is tightened by the operator, driving the adjustment wedge 108 into contact with the front flange 100 and rear annular member 102. The contact with the adjustment wedge 108 alters the relative inclination between the front flange 100 and the rear annular member 102, aligned the drive axis DA with the wheel rotational axis.

Preferably, a visual or audible indicator is utilized to provide the operator with an indication of when the relative inclination between the front flange 100 and rear annular member 102 has been sufficiently adjusted, as measured by the inclinometer 62, to reduce runout to within a predeter-
mended tolerance. For example, the operator may be instructed to turn the adjustment bolt 106 until a runout display 34G, shown in FIG. 2 turns from red to green.

As shown in FIG. 3, if it is desired to verify the accuracy of the compensation the operator may press a control button 34E, or similar input. Under control of the microprocessor 40, the variable speed spindle motor 16 slowly rotates the output spindle through an arc of approximately 120 degrees. The angular change between the resulting position and the previously compensation position is compared by the microprocessor 40. If the angular change is below a predetermined threshold, preferably an angular change equivalent to 0.002 inches of runout, the runout display 34G will remain green. If the angle change exceeds the threshold, the runout indicator 34G will turn red and it will be necessary for the operator to make additional runout compensation adjustments.

As shown in FIG. 13 through FIG. 15, an alternative prior art aligning joint 22 which may be utilized with the present invention comprises a front flange 150, configured to seat against the rotor-mounted adaptor 77 and configured for attachment to the output spindle 20. The front flange 150 is operatively coupled to the rear annular member 152 with a rotating connection. The connection between the front flange 150 and the rear annular member 152 is configured to permit adjustment of the relative inclination between the front flange 150 and the rear annular member 152, using a single adjustment bolt 154. Preferably, an alignment mark is included on the rear flange 152, associated with a predetermined adjustment position.

The adjustment bolt 154 is configured to seat within a bore 156 disposed in a resected portion 158 of the rear annular member 152, perpendicular to the drive axis DA. The bore 156 passes through the rear annular member 152, intersecting an adjusting chamber 160. The adjusting chamber 160 defines an opening in the front face 162 of the rear annular member 152, within which is seated an adjustment wedge 164. The adjustment wedge 164 is a rectangular block, seated within the adjusting chamber 160, having an adjustment surface 166 disposed adjacent the rear face 168 of the front flange 150, and an inclined longitudinal channel 170 on an opposite face. The inclined longitudinal channel 170 abuts a tapered portion 172 of the adjustment bolt 154 passing through the adjusting chamber 160. Axial movement of the adjustment bolt 154 within the bore 156 results in a sliding contact between the tapered portion 172 and the inclined longitudinal channel 170 of the adjustment wedge 164.

The adjustment wedge 164 is restrained against movement perpendicular to the drive axis DA by the interior surface of the adjusting chamber 160. Sliding contact between the adjustment wedge 164 and the adjusting chamber 160 results in movement of the adjustment wedge 164 parallel to the drive axis DA, either towards or away from the rear face of the front flange 150. The direction of movement is dependant upon the direction of the sliding contact. The resulting movement of the adjustment wedge 164 operates to alter the relative inclination between the front flange 150 and the rear flange 152, responsive to the adjustment of the single adjustment bolt 154, providing runout compensation in substantially the same manner of operation as the embodiment shown in FIG. 10 through FIG. 12.

During operation of an alternate embodiment of the on-car brake lathe 10, a cutting tip contact indicator circuit, shown in FIG. 16, provides an operator with a visual indication of contact between each cutting tip 201 and a surface 202 of a brake rotor 204. While described below in the context of an on-car brake lathe 10, those of ordinary skill in the art will recognize that the cutting tip contact indicator circuit described herein may be readily adapted and utilized for use with a bench brake lathe, such as shown at 200 in FIG. 17, and hence such an embodiment is considered within the scope of this invention.

Each cutting tip 201 is electrically coupled, to a power source 206, such as a battery, to an associated indicator circuit 208, and to an electrical ground 210. Contact between a cutting tip 201 and the brake rotor surface 202 completes an electrical circuit between the electrical ground 210 and the power source 206, resulting in an electrical current flow through an associated indicator circuit 208. Preferably, the associated indicator circuit 208 incorporates one or more LEDs 212, which are correspondingly illuminated by the flow of electrical current to provide the operator with a visual confirmation of contact between the cutting tip 201 and the brake rotor surface 202.

For some applications, it is desirable to provide an operator with a visual indication of a depth of cut for the cutting tips. In an alternate embodiment on-car brake lathe 10 of the present a visual indication is provided in the form of a numerical depth-of-cut display, but may take the form of a bar graph or other suitable visual measurement indication. Information provided to the operator on the depth-of-cut display is based on signals received at the microprocessor 40 from a rotary encoder 300 operatively coupled to the cutting head 18, as shown in FIG. 18. The rotary encoder 300 is disposed at an end of a threaded shaft 302 upon which the individual cutting tip holders 19 are disposed. Rotation of the threaded shaft 302 in a first direction moves each cutting tip holder 19 in a first direction, i.e., towards each other. Correspondingly, rotation of the threaded shaft 302 in the opposite direction moves each cutting tip holder 19 in the opposite direction, i.e. apart from each other. Each individual cutting tip holder 19 may be selectively locked in place relative to the threaded shaft 302 by a conventional locking mechanism 304, such that only one cutting tip holder 19 moves at a time.

To measure a depth-of-cut for a single cutting tip holder 19, the cutting tip 21 of a cutting tip holder 19 is initially moved into contact with the surface of a brake rotor 75. Upon contact, the signal from the rotary encoder 300 is either “zeroed” or recorded by the microprocessor 40. Subsequent movement of the cutting tip holder 19, as tracked by the signals from the rotary encoder 300, is displayed to the operator on a depth-of-cut display, and corresponds to a measured displacement from the previously “zeroed” or recorded position. The indication of initial contact between the cutting tip 21 and the vehicle brake rotor 75 may be either manually provided by an operator or automatically detected with a contact sensor signal as previously described. Once the desired depth-of-cut for the selected cutting tip holder 19 is reached, the cutting tip holder 19 is locked in place with the locking mechanism 304, and the process repeated for the second cutting tip holder 19 relative to the opposite face of the vehicle brake rotor 75.

The ability to predict the final thickness of a rotor after the selection of a desired depth of cut permits an operator to determine of the resulting final thickness will be less than a recommended minimum thickness, and to determine if the rotor should be replaced rather than resurfaced.

The cutting tip holder movement signal from the rotary encoder 300 may be further utilized by the microprocessor 40 to provide a thickness or displacement measurement between the two cutting tip holders 19 of the cutting head 18. To provide a displacement measurement, a calibration block of a predetermined thickness, such as 1.000 inches, is placed between the two cutting tip holders 19. The two cutting tip holders 19 are then moved to contact the associated cutting tips 21 with opposite sides of the calibration block. The open-
tor then indicates that the cutting tip holders 19 are in a calibration displacement, and the microprocessor 40 associates the current signal from the rotary encoder 300 to the predetermined size of the calibration block. Subsequent movement of the cutting tip holders 19, either relatively towards or away from each other, is registered by the rotary encoder 300, and used to calculate a current displacement distance between each of the cutting tip holders 19.

The displayed value of depth of cut may also be used by the operator to predict the final thickness of a vehicle brake rotor 75 after selection of a desired depth-of-cut, or to measure the amount of runout present in each face of the vehicle brake rotor 75. Vehicle brake rotor face runout is independent of the runout present between the mounting of the on-car brake lathe 10 and the wheel hub. A cutting tip 21 is brought into initial contact with the highest point on a vehicle brake rotor face, i.e. the point on having the greatest measure of lateral runout in an outward direction. At this point, the signal from the rotary encoder 300 may be associated with the peak runout, or “zeroed” by the microprocessor 40. Subsequent movement of the cutting tip 21 to the lowest point on the vehicle brake rotor 75, i.e. the point on having the least measure of lateral runout in an outward direction, and comparison of the signal from the rotary encoder 300 with the previously associated signal, provides an indication of runout present in that face of the vehicle brake rotor 75.

For some vehicle brake lathe applications, it is desirable for the brake lathe 10 to communicate with one or more remote vehicle service systems or computers. In an alternate embodiment, the microprocessor 40 of the on-car brake lathe 10 is operatively coupled to a communication circuit 56, such as a serial communications link, for exchanging information with a remote computer system, or one or more automotive service devices, such as a vehicle wheel aligner or a vehicle wheel balancer (not shown). The microprocessor 40 of the on-car brake lathe 10 is optionally configured to receive brake rotor specifications, such as diameter and thickness values, and may optionally be configured to communicate brake rotor resurfacing results to a remote display associated with the on-car brake lathe 10, or a remotely disposed printer or console. The microprocessor 40 may be further configured to utilize the received brake rotor specifications to establish limits on the range of linear movement for the cutting head 18, or to establish an initial cutting speed and linear feed rate for a variable speed spindle motor 16.

The present invention can be embodied in-part in the form of computer-implemented processes and apparatuses for practicing those processes. The present invention can also be embodied in-part in the form of computer program code containing instructions embodied in tangible media, such as floppy diskettes, CD-ROMs, hard drives, or an other computer readable storage medium, wherein, when the computer program code is loaded into, and executed by, an electronic device such as a computer, microprocessor or logic circuit, the device becomes an apparatus for practicing the invention.

The present invention can also be embodied in-part in the form of computer program code, for example, whether stored in a storage medium, loaded into and/or executed by a computer, or transmitted over some transmission medium, such as over electrical wiring or cabling, through fiber optics, or via electromagnetic radiation, wherein, when the computer program code is loaded into and executed by a computer, the computer becomes an apparatus for practicing the invention.

When implemented in a general-purpose microprocessor, the computer program code segments configure the microprocessor to create specific logic circuits.

In view of the above, it will be seen that the several objects of the invention are achieved and other advantageous results are obtained. As various changes could be made in the above constructions without departing from the scope of the invention, it is intended that all matter contained in the above description or shown in the accompanying drawings shall be interpreted as illustrative and not in a limiting sense.

The invention claimed is:
1. An on-car brake lathe system for resurfacing a brake rotor of a vehicle brake assembly, the brake lathe system having a support structure securing a drive motor, an adjustable cutting head, and output spindle adapted for coupling to a vehicle wheel hub and rotationally driven about a drive axis by the drive motor, further comprising:
   a sensor configured to produce at least one steady-state measurement indicative of runout present between the output spindle stopped at an associated discrete rotational position and the vehicle wheel hub;
   a rotational position detector configured to produce a signal representative of the discrete rotational position of said output spindle about the drive axis, associated with the steady-state measurement indicative of runout from the sensor;
   a microprocessor configured to receive a plurality of said steady-state measurements and associated discrete rotational position signals, and to calculate a runout characteristic between the output spindle and the vehicle wheel hub.
2. The brake lathe system of claim 1 further including an aligning joint coupled between the output spindle and the vehicle wheel hub.
3. The brake lathe system of claim 2 wherein said aligning joint includes:
   a mounting flange coaxially coupled to the output spindle;
   an annular member coaxially coupled to said mounting flange at an adjustable inclination; and
   an adjustment element disposed between said mounting flange and said annular member radially outward from said drive axis, said adjustment element configured to alter an inclination between said mounting flange and said annular member.
4. The brake lathe system of claim 3 further including an adjustment mechanism configured to alter a position of said adjustment element parallel to said drive axis.
5. An on-car brake lathe system for resurfacing a brake rotor of a vehicle brake assembly, the brake lathe system having a support structure securing a drive motor, an adjustable cutting head, and output spindle adapted for coupling to a vehicle wheel hub and rotationally driven about a drive axis by the drive motor, further comprising:
   a sensor configured to produce a steady-state measurement indicative of runout present between the output spindle and the vehicle wheel hub at a discrete rotational position;
   a rotational position detector configured to produce a signal representative of a discrete rotational position of said output spindle;
   a microprocessor configured to receive a plurality of said steady-state measurements and associated discrete rotational position signals, and to calculate a runout characteristic between the output spindle and the vehicle wheel hub;
   an aligning joint coupled between the output spindle and the vehicle wheel hub;
   said aligning joint includes a mounting flange coaxially coupled to the output spindle, an annular member coaxially coupled to said mounting flange at an adjustable
inclination, and an adjustment element disposed between said mounting flange and said annular member radially outward from said drive axis, said adjustment element configured to alter an inclination between said mounting flange and said annular member; and an adjustment mechanism configured to alter a position of said adjustment element, parallel to said drive axis, including a tapered adjustment bolt in engagement with said adjustment element, said tapered adjustment bolt oriented perpendicular to said drive axis.

6. An on-car brake lathe system for resurfacing a brake rotor of a vehicle brake assembly, the brake lathe system having a support structure securing a drive motor, an adjustable cutting head, and output spindle adapted for coupling to a vehicle wheel hub and rotationally driven about a drive axis by the drive motor, further comprising:
a sensor configured to produce a steady-state measurement indicative of runout present between the output spindle and the vehicle wheel hub at a discrete rotational position; a rotational position detector configured to produce a signal representative of a discrete rotational position of said output spindle; a microprocessor configured to receive a plurality of said steady-state measurements and associated discrete rotational position signals, and to calculate a runout characteristic between the output spindle and the vehicle wheel hub;
an aligning joint coupled between the output spindle and the vehicle wheel hub, said aligning joint including a mounting flange coaxially coupled to the output spindle, an annular member coaxially coupled to said mounting flange at an adjustable inclination, and an adjustment element disposed between said mounting flange and said annular member radially outward from said drive axis, said adjustment element configured to alter an inclination between said mounting flange and said annular member; and wherein said adjustment element including a wedge secured between said annular member and said mounting flange, said wedge configured for movement parallel to said drive axis.

7. The brake lathe system of claim 2 wherein said microprocessor is further configured to control actuation of the drive motor to rotate said aligning joint to an adjustment position responsive to said calculated runout characteristic.

8. A method for measuring lateral runout between a rotational axis of an on-car brake lathe output spindle and a rotational axis of a vehicle wheel hub assembly to which the on-car brake lathe output spindle is operatively coupled by an adapter for the resurfacing of a vehicle wheel brake rotor, comprising:

obtaining at least three steady-state measurements of characteristics associated with the operative coupling between the on-car brake lathe output spindle and the vehicle wheel hub assembly, each steady-state measurement obtained when the output spindle is stationary at an associated discrete rotational position about the drive axis;
calculating a sinusoidal representation of runout between the rotational axis of the on-car brake lathe output spindle and the rotational axis of the vehicle wheel hub assembly from said at least three steady-state measurements and associated rotational positions.

9. A method for runout compensation between a brake rotor and a brake lathe system having an adjustment element including an annular member coupled between an output spindle of the brake lathe and a vehicle wheel hub assembly, comprising:

obtaining at least three steady-state measurements of runout between said output spindle and the vehicle wheel hub assembly, each of said at least three steady-state measurements obtained with the output spindle stationary and at associated rotational positions about the drive axis;
identifying a single runout compensation rotational position from said at least three measurements and associated rotational positions;
rotating said output spindle to said identified runout compensation rotational position;
actuating said adjustment element to alter an axial inclination between the output spindle and the vehicle wheel hub assembly.

10. The method for runout compensation of claim 9 further including the step of establishing the output spindle and the annular member in a parallel configuration.

11. An improved brake lathe system for resurfacing a workpiece, the brake lathe system including a pair of linearly adjustable cutting tips configured to engage one or more surface of the workpiece, the improved comprising:
at least one vibration sensor operatively configured to detect vibrations associated with contact between at least one of the cutting tips and the workpiece surface and to generate a signal representative of said detected vibrations;
a cutting tip contact indicator circuit configured to receive said signal representative of said detected vibrations and wherein said cutting tip contact indicator circuit is further configured to provide a visual indication of contact between at least one of said cutting tips and a surface of the workpiece responsive to receipt of said signal.

12. The improved brake lathe system of claim 11 wherein said cutting tip contact indicator circuit incorporates an audio component configured to provide an audible indication of contact between at least one of said cutting tips and the workpiece surface responsive to said signal representative of said detected vibrations.

13. An improved brake lathe for resurfacing a brake component of a vehicle brake assembly, the brake lathe having an adjustable cutting head supporting first and second cutting tips in an adjustable, linearly spaced, configuration, said first and second cutting tips selectively coupled to a threaded shaft for coxial linear movement responsive to, and proportional to, rotational movement of the threaded shaft, the improvement comprising:
a rotational position sensor operatively coupled to said threaded shaft, said sensor configured to generate a signal representative of a current rotational position of said threaded shaft;
a microprocessor operatively coupled to said sensor to receive said rotational position signal, said microprocessor configured to utilize a plurality of received rotational position signals, representative of a change in rotational position of said threaded shaft, to calculate a displacement measurement associated with linear movement of at least one of the first and second cutting tips proportional to said change in said rotational position of said threaded shaft; and wherein said microprocessor is configured to display said displacement measurement on a measurement display.

14. The improved brake lathe of claim 13 wherein said displacement measurement is a depth of cut measurement for
19. The improved brake lathe of claim 13 wherein said plurality of received rotational position signals define at least one reference position signal.

16. The improved brake lathe of claim 13 wherein said plurality of received rotational position signals define at least one calibration position signal.

17. A brake lathe for resurfacing a brake component of a vehicle brake assembly, comprising:
an output spindle adapted to couple the brake lathe to the brake component;
a linearly adjustable cutting head configured with first and second cutting tips for engagement with a surface of the brake component;
a drive motor operatively coupled to at least said output spindle to drive said output spindle and the brake component about a rotational axis;
a microprocessor configured with software instructions for control of said drive motor and said linearly adjustable cutting head;
a communications circuit configured to communicate with at least one remote vehicle service device external to the brake lathe; and
wherein said microprocessor is further configured to utilize said communication circuit to receive brake specification data associated with the resurfacing of a brake component from said at least one remote vehicle service device.

18. The brake lathe of claim 17 wherein said microprocessor is further configured to utilize said received brake component specification data to establish a limit on a range of movement for said linearly adjustable cutting head.

19. The brake lathe of claim 17 wherein said drive motor is a variable speed drive motor, and wherein said microprocessor is further configured to utilize said received brake component specification data to establish an initial rotational speed for said variable speed drive motor to drive said output spindle and the brake component.

20. The brake lathe of claim 17 wherein said drive motor is a variable speed drive motor, and wherein said microprocessor is further configured to utilize said received brake component specification data to establish an initial linear feed rate for said adjustable cutting head.

21. The brake lathe of claim 17 wherein said microprocessor is further configured to communicate at least one brake component resurfacing result to said at least one external device.

22. An on-car brake lathe for resurfacing a vehicle brake component coupled to a vehicle wheel hub assembly, comprising:
a support structure;
a drive motor secured to said support structure;
an output spindle rotationally driven by said drive motor, said output spindle adapted to couple to the vehicle wheel hub assembly;
at least one inclination sensor responsive to an angle of inclination of said support structure relative to gravity to generate a signal representative of an inclination of said support structure; and
a microprocessor operatively coupled to said at least one inclination sensor to receive said signal, said microprocessor configured to control said drive motor responsive to said signal representing an inclination of said support structure exceeding a predetermined value to stop rotation of said drive motor.

23. An on-car brake lathe for resurfacing a vehicle brake component coupled to a vehicle wheel hub assembly, comprising:
a support structure;
a drive motor secured to said support structure;
an output spindle mounted to said support structure and rotationally driven about a drive axis by said drive motor, said output spindle adapted to couple to the vehicle wheel hub assembly; and
an operator console rotationally coupled to said support structure on an axis parallel to said drive axis and wherein said operator console is rotationally independent of said output spindle and inclination of said support structure to maintain a selected inclination relative to gravity.

24. The on-car brake lathe of claim 23 wherein said operator console includes an operator interface having at least one display element adapted to provide a visual display of data to an operator and at least one input control adapted to receive input from said operator.
